Testing the Significance of Class Refinement

Leigh J. Halliwell, FCAS, MAAA

Abstract

Generalized linear modeling (GLM) is becoming a regular tool for insurance ratemaking. Actuaries and underwriters have begun to realize that classes may not simply interact, whether additively or multiplicatively. Some class combinations may synergize, or more than simply interact; others may counteract, or less than simply interact. But lest actuaries be tempted by abundant computer power and affordable GLM software to over-refine rating classes, they must know how to test whether class refinement is statistically significant. This paper provides the theory for this testing, and performs an illustrative test on a small dataset of automobile physical-damage claims.

Mr. Halliwell is a consulting actuary in Chattanooga, TN, with EPIC Consulting, LLC. His phone and e-mail are 423-296-2739 and Ihalliwell@ask-epic.com.

Keywords: generalized linear modeling, classification, hypothesis testing, significance

Testing the Significance of Class Refinement

Leigh J. Halliwell, FCAS, MAAA

One benefit of generalized linear modeling (GLM) is that with it one can test whether the explanatory power of a model with more classes is significantly greater than that of a model with fewer classes. In other words, one can scientifically determine whether a refinement of a classification scheme is worthwhile. This article presents basic statistical theory, and illustrates class-refinement testing with a simple exercise.

The exercise is to estimate frequencies of automobile physical-damage claims by state, sex, and age, a reasonable prerequisite to rating an auto owner's physical-damage insurance coverage. Exhibit 1 shows the summarized data for five states, two sexes, and four age groups. Since every combination is represented, there are $5 \times 2 \times 4 = 40$ observations. As per the bottom of Exhibit 2, young insureds are less than twenty-one years old; those in their prime are from twenty-one to forty; middle age ranges from forty-one to sixty-five; and old age is over sixty-five. The age groupings and the data itself are purely illustrative.

A standard actuarial treatment might summarize the exposures and claim counts as in Exhibit 2. It is usual to select certain classes as base, here the base being females in their prime (i.e., from twenty-one to forty years of age). In this dataset the frequency of males is 1.073 times that of females. Frequency decreases by

age until old age, the relativities being 1.899, 1.000 (base), 0.825, and 1.142. One can combine these "one-way" relativities to derive that the PD-frequency of old-aged males, for example, is 1.072 × 1.142 = 1.225 times the base frequency. However, one can just as reasonably calculate one table of "two-way" relativities, and conclude that the old-aged-male frequency is 1.288 times greater than base. If premium were proportional to PD-frequency, the "two one-way or one two-way" decision would make a 4.8 percent difference in the premiums of old-aged males.

The two one-way factors require six relativities, or more accurately, four after allowing for one base per factor. The one two-way factor requires eight relativities, or seven without the base. Combining many one-way factors is simpler and easier than using one many-way factor; but it is also less accurate. Only a statistical model can test whether the loss of accuracy is significant. Moreover, in Exhibit 2 sex and age are not controlled for state; but a statistical model can filter out the effect of state.

The standard linear model is $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}$, where \mathbf{y} is the $(t \times 1)$ vector of observations, \mathbf{X} is the $(t \times k)$ "design" matrix, each of whose columns is called a factor or explanatory variable, $\boldsymbol{\beta}$ is the $(k \times 1)$ vector of parameters to be estimated, and \mathbf{e} is the $(t \times 1)$ random vector of error terms. The errors are assumed to be of mean zero, of identical variance (i.e., "homoskedastic"), and of zero covariance. In matrix terminology, the error vector has mean 0 $(t \times 1)$ and variance $\sigma^2 \mathbf{I}_1$, where \mathbf{I}_1 is the $(t \times t)$ identity matrix. The columns of \mathbf{X} must be

linearly independent, i.e., X must be of full column rank. Since the k columns of X explain, or account for, the t observations (with a residue of randomness), it is desirable for t to be much larger than k. With the model so described, the best linear unbiased estimator (BLUE) of β is $\beta = (X'X)^T X'y$. The variance of this estimator, which will be important for hypothesis testing, is $Var[\beta] = \sigma^2(X'X)^T$. Usually σ^2 must be estimated, the formula for the unbiased estimator being:

$$\sigma^2 = \frac{(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{t - k}$$

Exhibit 3 presents and solves the one-way model. The design matrix consists of zeroes and ones. Therefore, the explanatory variables are categorical. For example, the first column of X tells whether the observation pertains to California (yes = 1, no = 0). The last column tells whether the observation pertains to oldaged insureds. There are no columns for the base classes of female and prime; hence, nine variables account for as much as possible of forty observations, leaving thirty-one degrees of freedom in the estimation of σ^2 . One reads down the exhibit through the intermediate calculations of X'y and X'X to $(X'X)^{-1}$ and β . Below that is the estimate of the variance of β . To the right of the design matrix are predicted values and residuals, and below these are sums of squares and cross products. From these we conclude that the model explains 99.6 percent of the actual values, and that the estimate for σ^2 is 0.049.

The logarithm of frequency is here modeled as a linear combination of parameters with an error term, i.e., $\ln \phi = X\beta + e$. Thus, $\phi = exp(X\beta + e)$. The exponential function is a monotonic link between frequency and a standard linear model, and it is this link that makes for a generalized linear model (GLM). Sex and age-group relativities, displayed in the "One-Way" table at the bottom of Exhibit 5 are exponentiated β values, e.g., the old-age relativity is exp(0.261) = 1.298. This relativity, for which state and age have been controlled, is much larger than the naïve relativity of 1.142.

Similarly, Exhibit 4 works out the two-way model, with its five state parameters and seven combinations of sex and age group (S × AG). Having three more explanatory variables, it explains more than the one-way model (99.7 versus 99.6 percent). However, due to its fewer degrees of freedom its estimated σ^2 exceeds that of the one-way model (0.051 versus 0.049). Exhibit 5 shows that each model outpredicts the other exactly half the time, and neither method prevails on average or squared deviations. At this point most would claim, quite rightly, that the accuracy gain of the two-way model is trifling, and would prefer multiplying the two one-way factors. However, this is an imprecise, unscientific judgment, and it makes a sizeable difference to the relativities of females in their middle age and males in their prime (13.8 and 12.7 percent, according to Exhibit 5).

The key to the hypothesis is the recognition that the one-way model is a subset of the two-way. Let index i range over female and male, and index j over young,

prime, middle, and old. And let β_i be the one-way factor for sex, β_i the one-way factor for age group, and β_{ij} the two-way factor for the combination of sex and age group. The two-way model reduces to the one-way if and only if for all $i \in \{1,2\}$ and for all $j \in \{1,2,3,4\}$, $\beta_{ij} = \beta_i + \beta_j$. Now, because they are bases, β_{i-1} , β_{j-2} , and β_{ij-12} are zero, and are not paired with explanatory variables. The proper form of the hypothesis must eliminate all β_i and β_j variables, and contain constraints on β_{ij} variables only. The bases allow us to achieve the form. For i=1 and for all j, $\beta_{1j} = \beta_{1-1} + \beta_j = 0 + \beta_j = \beta_j$. And for j=2 and for all i, $\beta_{12} = \beta_i + \beta_{j-2} = \beta_i + 0 = \beta_i$. Therefore, for all i and j, $\beta_{ij} = \beta_{12} + \beta_{1j}$. However, some of these equations are non-binding tautologies. In particular, for i=1, $\beta_{1j} = \beta_{12} + \beta_{1j} = 0 + \beta_{1j} = \beta_{1j}$. This leaves constraints of the form $\beta_{2j} = \beta_{22} + \beta_{1j}$. But even here, when j=2 we have the tautology $\beta_{22} = \beta_{22} + \beta_{12} = \beta_{22} + 0 = \beta_{22}$. Therefore, the two-way model reduces to the one-way when subjected to the three constraints (corresponding to its three fewer degrees of freedom):

$$\beta_{21} = \beta_{22} + \beta_{11}$$

$$\beta_{23} = \beta_{22} + \beta_{13}$$

$$\beta_{24} = \beta_{22} + \beta_{14}$$

Expressed in matrix notation, the hypothesis H₀ that the two-way model is equivalent to a one-way is:

$$\begin{bmatrix} 1 & 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 & -1 \end{bmatrix} \begin{bmatrix} \beta_{11} \\ \beta_{13} \\ \beta_{24} \\ \beta_{21} \\ \beta_{22} \\ \beta_{23} \\ \beta_{24} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

$$R_{(3\times7)}\beta_{(7\times1)} = r_{(3\times1)}$$

Matrix R appears in Exhibit 7, but augmented with five columns of zeros to accommodate the state parameters.

Before developing the statistic for testing this hypothesis, it is instructive to see how the two-way model of Exhibit 4 under the constraint $R\beta = r = 0$ reduces to the one-way model of Exhibit 3. In an earlier article[†] the author showed that the restricted BLUE β^* of the model $y = X\beta + e$ subject to the constraint $R\beta = r$ falls out of the equation:

$$\begin{bmatrix} X'X & R' \\ R & 0 \end{bmatrix} \begin{bmatrix} \beta' \\ \lambda' \end{bmatrix} = \begin{bmatrix} X'\mathbf{y} \\ r \end{bmatrix}$$

One can discern this form in the three additional rows and columns of the middle section of Exhibit 6. The three lambdas are Lagrange multipliers, byproducts of the constrained least-squares problem that may be ignored. One may check that the seven sex-age parameters are sums of the proper sex and age-group

Leigh J. Halliwell, "Statistical and Financial Aspects of Self-Insurance Funding," <u>Alternative Markets/Self Insurance</u> (CAS 1996 Discussion Paper Program), 1-46. Appendix A and its citations not only solve the restricted least-squares problem, but provide proofs for all the statements herein to follow.

parameters of Exhibit 3. But the equivalence of the two models is apparent from their identical predictions (the X β columns) and σ^2 estimates.

The statistical test makes use of the fact the least-squares estimator β has mean β and variance $\sigma^2(X'X)^{-1}$. Therefore, $R\beta$ has mean $R\beta$ and variance $\sigma^2R(X'X)^{-1}R'$. Also important is the assumption that the distribution of β is multivariate normal. This is true, if e is multivariate normal; but even under certain robust conditions the distribution of β will be asymptotically multivariate normal. Then $R\beta$ will be multivariate normal with mean $R\beta$ and variance $\sigma^2R(X'X)^{-1}R'$, and $R\beta-R\beta$ multivariate normal with mean zero and variance $\sigma^2R(X'X)^{-1}R'$. Wherefore it follows that the expression

$$(R\beta - R\beta)(\sigma^2R(X'X)^{-1}R')^{-1}(R\beta - R\beta)$$

is chi-square distributed with j degrees of freedom, where j is the number of rows of R. However, normally we do not know σ^2 and have to estimate it. But the sum of the squared residuals divided by σ^2 is chi-square distributed with $\ell-k$ degrees of freedom, and this sum does not covary with β . Therefore, under the multivariate normal assumption, the following two expressions are independent chi-square random variables:

$$\frac{(R\boldsymbol{\beta} - R\beta)(R(X'X)^{-1}R')^{-1}(R\boldsymbol{\beta} - R\beta)}{\sigma^2}$$

$$\frac{(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{\sigma^2} = \frac{\sigma^2}{\sigma^2}(t - k)$$

Finally, this implies that the following expression is approximately and asymptotically F-distributed with j and t-k degrees of freedom:

$$\frac{\left(\mathbf{R}\boldsymbol{\beta} - \mathbf{R}\boldsymbol{\beta}\right)\left(\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}'\right)^{-1}\left(\mathbf{R}\boldsymbol{\beta} - \mathbf{R}\boldsymbol{\beta}\right)}{\sigma^{2}} / j}{\frac{\left(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\right)\left(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\right)}{\sigma^{2}} / t - k} = \frac{\left(\mathbf{R}\boldsymbol{\beta} - \mathbf{R}\boldsymbol{\beta}\right)\left(\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}'\right)^{-1}\left(\mathbf{R}\boldsymbol{\beta} - \mathbf{R}\boldsymbol{\beta}\right) / j}{\sigma^{2}}$$

Hence, under hypothesis H_0 : $R\beta = r$, the statistic

$$\frac{(R\beta - R\beta)(R(X'X)^{-1}R')^{-1}(R\beta - R\beta)/j}{\sigma^2}$$

is F-distributed with j and t - k degrees of freedom:

Accordingly, Appendix 7 tests whether the β of the two-way model differs significantly from the β of the one-way model, which is the two-way β under hypothesis H₀. R is a 3×12 matrix of zeroes and ones, and r is the 3×1 zero vector. X is the design matrix of Appendix 4, from which β , (X'X)⁻¹ and σ^2 also are taken. The F statistic as described above has the value 0.546, which is at the 65.5 percentile of the F_{3, 28} distribution. In other words, if H₀ be true, in approximately one-third of repeated samples will the F statistic be greater than 0.546. Few statisticians would deem 65.5 percent as significant enough to reject the hypothesis; most would here accept the simpler, one-way model.
